Wenlan Tian COP 3530 Section 1087, MAEB 211 12/09/2014 Project 2V

## **ABSTRACT**

The purpose of this project is to compare the performance of different hash functions, capacity effects, collision avoidance methods, open addressing vs randomized binary search tree. By comparing the mean system time and user time of four different hash functions, the hash\_string\_2 provided by the professor ran the fastest, and the hashed keys are relatively even distributed across all the slots. Thus, the hash\_string\_2 function was used in the other parts of the project. The second part of the project is to test the best capacity for the hash\_string\_2 function among all the datasets. However, it was incompleted, nor the remaining parts.

## HONESTY PLEDGE

"On my honor, I have neither given nor received unauthorized aid in doing this assignment."

#### LEARNING EXPERIENCE

The most difficult parts of the task to design the experiment because there are so many different factors involved.

The easiest part of the task is to implement it once the design has done, however, there are still many coding issues need to be solved.

The assignment's educational objective: test the effects of different factors for hash maps. Also be familiar with GNUPLOT.

How well I think I achieved them: I've tried my best, but I still can only finish the first part. I started the second part, but there is some bugs in the code so that I was unable to get the results. I did not even have time to start the other parts.

#### INTRODUCTION

When dealing with programming, running time is an important factor we should think about. For a hash map, there are many factors could affect the speed of the program: hash function, capacity, methods for handling collisions, etc.

The purposes of this project are: 1) identify the best performing hash function for keys of type string; 2) identify the best performing heuristic for selecting a hash table capacity when using the best performing hash function for keys of type string; 3) identify the best performing collision avoidance strategy when using the best table capacity selection heuristic and the best performing hash function for keys of type string; 4) characterize the relationship between number of buckets and performance relative to the best open addressing scheme's performance; 5) compare the performance of your randomized binary search tree (BST) implementation to both the "best" performing open addressing hash map and the hash map with buckets.

The performance of hash map depends on a lot of factors, such as the hash function, capacity, collision handling methods and many others. The goal of this research will help to understand how these factors affect the performance, and thus we can choose the best one for real programming project.

#### **OVERVIEW**

The best hash function will be first determined, and the best hash table capacity will be selected based using the previous "best" hash function. After that, the best collision avoidance strategy will be determined. At last, the performance between randomized BST and open addressing map will be compared.

## TEST PLATFORM AND CONDITON

The tests in this project were performed on OpenBSD 5.5, and figures were constructed using GNUPLOT which is already built in the OpenBSD 5.5.

## 1. HASH FUNCTION PERFORMANCE

## **Objective**

The part is specifically to identify the best performing hash function for keys of type string.

## **Experimental protocol**

In this part, four hash functions for type string were tested, including my own hash function in previous project and another three functions provided by the instructors.

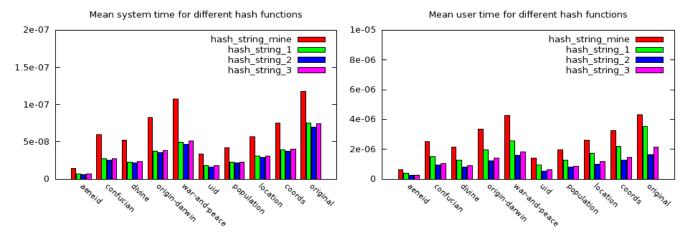

These three functions were tested individually using ten different data sets with the capacity the same as the total number of items in each data set respectively.

More detailed, the mean time to hash a key in dataset i using function for each {hash set + hash function} paring were tested. Thus the mean user time and system time were output from a total of 40 data set and hash function pairs. After that, the mean time to hash a key for each hash function across all the data sets were computed as well.

A total of ten data sets were used for this test, including aeneid\_vergil-unique.txt, confucian-analects-unique.txt, divine-comedy\_dante-unique.txt, origin-of-the-species\_darwin-unique.txt, war-and-peace\_tolstoi-unique.txt, localities-uid.txt, localities-population.txt, localities-location.txt, localities-coords.txt, and localities-original.txt.

## **Results**

For each dataset, both the mean system time and user time to hash a key in every dataset were tested when using four functions. The histogram below shows that the hash\_string\_2 function took the least time compared to other three functions in all the ten data sets for both user time and system time.

After that, the performance of each hash functions was tested across all the data sets. The shortest time, 1<sup>st</sup> quarter time, mean time, 3<sup>rd</sup> quarter time, and the longest time were used calculated, and a box-and-whisker wth median bar and whiskerbars graph were draw using the GNUPLO. From the graph, it also showed that hash\_string\_2 function has the least system time and user time overall. The deviations of the time for hash\_string\_2 are also the least compared to other three functions.

A good hash function should have the hashed keys evenly distributed across the map. Thus, for each dataset, Pearson's cumulative test statistic test was performed to evaluate the performance of the distribution of each function using 13 different capacities (Table 1). The figures below showed that, for 7 out of 10 data sets, hash\_function\_1 has the worst performance (highest X2) for almost all the capacities, while the other three functions have similar performance. For data set "war and peace", hash\_function\_1 showed different performance pattern for different capacity. For data set "localities-original", all the four functions have similar performance.

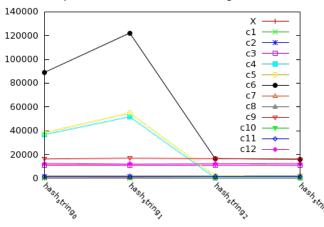

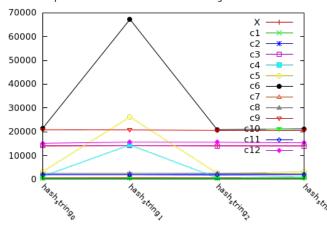

Chi-square of different hash function using war-and-peacetolstoi-unique.txt

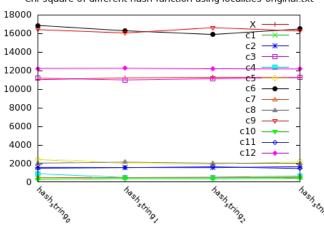

Chi-square of different hash function using localities-uid.txt

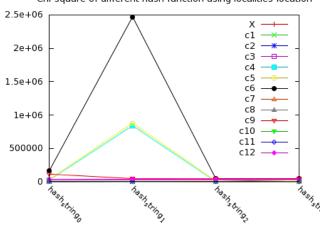

Chi-square of different hash function using localities-location.txt

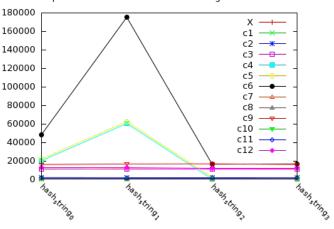

Chi-square of different hash function using localities-original.txt

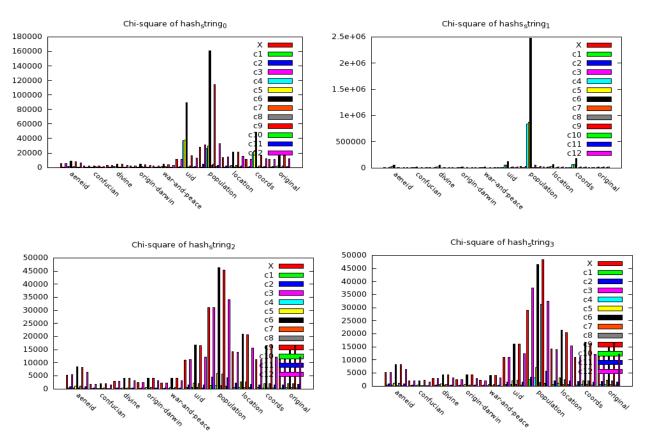

Chi-square of different hash function using localities-location

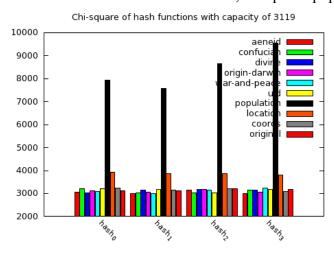

Chi-square of different hash function using localities-coords.txt

For each hash function, the Chi-square test was also performed across all the ten data sets and 13 table capacities. From the four histograms shown below, the distribution of hash\_string\_2 and hash\_string\_3 are more even than hash\_string\_0 and hash\_string\_1. That means hash\_string\_2 and hash\_string\_3 will do good not depend on the data set and capacity very much, which is good for hashing.

For a given capacity of 3119, the performance of all the four hash functions was tested across ten data sets. The histogram bellowed there no significant difference for the hash functions across most of the data sets, except the population data set.

#### **Conclusions**

How quickly does a particular function compute a hash for keys of type K?

As mentioned before, for each dataset, both the mean time to hash a key in every dataset were tested using four functions. The results showed that the hash\_string\_2 function took the least time compared to other three functions in all the ten data sets for both user time and system time. The performance of each hash functions was also tested across all the data sets, and the result showed that hash\_string\_2 function has the least mean time overall.

How well does a particular hash function for keys of type K, perform at randomly distributing those keys for a table capacity of n for each of the data sets?

For each dataset, Pearson's cumulative test statistic test was performed to evaluate the performance of the distribution of each function using 13 different capacities. The result showed hash\_function\_1 has the worst performance across the most of the data sets while the other three functions have the similar performance.

For data sets with keys of type K, which hash function does the best over-all job?

For each hash function, the Chi-square test was performed across all the ten data sets and 13 table capacities. The result showed the distribution of hash\_string\_2 and hash\_string\_3 are more even than hash\_string\_0 and hash\_string\_1. That means hash\_string\_2 and hash\_string\_3 will do good not depend on the data set and capacity very much, which is good for hashing.

For data sets with keys of type K, which hash function does the best over-all job for a table capacity of 3119?

With a given capacity of 3119, the performance of all the four hash functions was tested across ten data sets. The results showed there no significant difference for the hash functions across most of the data sets, except the population data set.

Based on the all above test, hash\_string\_2 has the most performance overall, which took least time for hashing, and showed even distribution for the hashed keys.

## 2. OPEN ADDRESSING HASH MAP PERFORMANCE: CHOOSING A MAXIMUM CAPACITY

## **Objective**

This part is specifically to identify the best performing heuristic for selecting a hash table capacity when using the best performing hash function for keys of type string.

## **Experimental protocol**

Five kinds of capacity will be tested based on the original unique number of items in the data set. These include: (M is 0.95 \* Number of unique items)

- 1) M + aM, where  $0 \le a \le 1.0$
- 2) N, where N, is the "closest" ( $\geq$ ) prime to (M + aM), where  $0 \leq a \leq 1.0$

- 3) N, where N is the closest, power of two  $\geq$  M
- 4) N, where N is the prime that is "closest" to the closest power of two  $\geq$  than M
- 5) N, where N is a prime that is  $\geq M$  and "closest" to being half-way between the nearest powers of two bounding M above and below.

Depending on different value of a, the first two type of capacity will vary, but the other three are the same (Table 2).

Table 2: capacity table

	No.uniqu e lexeme	M = 0.95* No.uniqu e lexeme	M + a M	Closest $(\geq)$ prime to $(M + aM)$	Closest power of two $\geq M$	Prime "closest" to the closest power of two $\geq$ than $M$	Prime $\geq M$ and "closest" to being half-way between the nearest powers of two bounding $M$ above and below

## **Results**

## **Conclusions**

For a given load factor, how does each table size choice perform for each of the data sets?

For a given load factor, how does each table size choice perform overall for data sets using keys of type *K*?

For data sets with keys of type *K*, which table size choice has the best over all *balance* between performance and memory required (assuming the table's size will never exceed M)?

- 3. Open addressing hash map performance: collision handling strategies
  The part is specifically to identify the best performing collision avoidance strategy when using the best table capacity selection heuristic and the best performing hash function for keys of type string.
- 4. Hash map performance: buckets vs open addressing

The part is specifically to characterize the relationship between number of buckets and performance relative to the best open addressing scheme's performance

## 5. Hash map vs randomized BSTs

The part is specifically to identify the "best" performing collision avoidance strategy when using the "best" table capacity selection heuristic and the "best" performing hash function for keys of type K.

# 3. OPEN ADDRESSING HASH MAP PERFORMANCE: COLLISION HANDLING STRATEGIES

## **Objective**

This part is specifically to identify the best performing heuristic for selecting a hash table capacity when using the best performing hash function for keys of type string.

## **Experimental protocol**

#### Results

#### **Conclusions**

#### 4. HASH MAP PERFORMANCE: BUCKETS VS. OPEN ADDRESSING

## **Objective**

This part is specifically to characterize the relationship between number of buckets and performance relative to the "best" open addressing scheme's performance.

## **Experimental protocol**

## Results

#### **Conclusions**

#### 5. HASH MAP VS. RANDOMIZED BSTs

## **Objective**

This part is specifically to compare the performance of your randomized binary search tree implementation to both the "best" performing open addressing hash map and the hash map with buckets.

## **Experimental protocol**

## Results

## **Conclusions**

#### **CONCLUSION**

Only the first part of the project is completely done which shows the hash\_string\_2 function provided by the professor had the best overall performance among different data sets and capacity.
